

Dirichlet Process Mixtures of Generalized Linear Models

Lauren A. Hannah, David M. Blei, Warren B. Powell

July 16, 2010

Abstract

We propose Dirichlet Process mixtures of Generalized Linear Models (DP-GLM), a new method of nonparametric regression that accommodates continuous and categorical inputs, and responses that can be modeled by a generalized linear model. We prove conditions for the asymptotic unbiasedness of the DP-GLM regression mean function estimate. We also give examples for when those conditions hold, including models for compactly supported continuous distributions and a model with continuous covariates and categorical response. We empirically analyze the properties of the DP-GLM and why it provides better results than existing Dirichlet process mixture regression models. We evaluate DP-GLM on several data sets, comparing it to modern methods of nonparametric regression like CART, Bayesian trees and Gaussian processes. Compared to existing techniques, the DP-GLM provides a single model (and corresponding inference algorithms) that performs well in many regression settings.

1 Introduction

In this paper, we examine the general regression problem. The general regression problem models a response variable Y as dependent on a set of covariates x ,

$$Y | x \sim f(m(x)). \quad (1)$$

The function $m(x)$ is called the *mean function*, which maps the covariates to the conditional mean of the response; the distribution f characterizes the deviation of the response from its conditional mean. The simplest example of general regression is linear regression, where $m(x)$ is a linear function of x and f is a Gaussian distribution with mean $m(x)$ and fixed variance.

The linear regression methodology is generalized to many types of response variables with *generalized linear models* (GLMs) (McCullagh and Nelder 1989). In their canonical form, a GLM assumes that the conditional mean of the response is a linear function of the covariates and that the response distribution is in an exponential family. GLMs generalize many classical regression and classification methods beyond linear regression, including logistic regression, multinomial regression, and Poisson regression.

A considerable restriction imposed by a GLM is that the covariates must enter the distribution of the response through a linear function. (A non-linear function can be applied to the output of the linear function, but only one that does not depend on the covariates.) For real world applications where the distribution of the response depends on the covariates in a non-linear way, this assumption is limiting. Flexibly fitting non-linear response functions is the problem of *nonparametric regression*.

Our goal in this paper is to develop a general-purpose method for nonparametric regression. We develop an algorithm that can capture arbitrarily shaped response functions, model diverse response types and covariate types, accommodate high dimensional covariates, and capture heteroscedasticity, i.e., the property of the response distribution where both its mean and variance change with the covariates.

Our idea is to model $m(x)$ by a mixture of simpler “local” response distributions $f_i(m_i(x))$, each one applicable in a region of the covariates that exhibits similar response patterns. To handle multiple types of responses, each local regression is a GLM. Notice this means that each $m_i(x)$ is a linear function—the desired non-linear mean function arises when we marginalize out the uncertainty about which local response distribution is in play. (See Figure 1 for a simple example with one covariate and a continuous response function.) Furthermore, our method captures heteroscedasticity. Each GLM f_i can vary in a way beyond the variability that arises from a single linear function of the covariates.

Finally, we take a Bayesian nonparametric approach to determining the number of local regressions needed to explain, and form predictions about, a particular data set. With a Bayesian nonparametric mixture model, we let the data determine both the number and form of simple mean functions that are mixed. This is critical for the objective of modeling arbitrary response distributions: complex response functions can be constructed with many local functions, while simple response functions need only a small number. Unlike frequentist nonparametric regression methods, e.g., those that create a mean function for each data point, the Bayesian nonparametric approach is biased to using only as complex a model as the data allow.

Thus, we develop *Dirichlet process mixtures of generalized linear models* (DP-GLMs), a Bayesian nonparametric regression model that combines the advantages of generalized linear models with the flexibility of nonparametric regression. DP-GLMs are a generalization of several existing DP-based, covariate/response specific regression models (Müller et al. 1996, Shahbaba and Neal 2009) to a variety of response distributions. We derive Gibbs sampling algorithms for fitting and predicting with DP-GLMs. We investigate some of the statistical properties of these models, such as the form of their posterior and conditions for the asymptotic unbiasedness of their predictions. We study DP-GLMs with several types of data.

In addition to defining and discussing the DP-GLM, a central contribution of this paper is our theoretical analysis of its response estimator and, specifically, the asymptotic unbiasedness of its predictions. Asymptotic properties help justify the use of certain regression models, but they have largely been ignored for regression models with Dirichlet process priors. We will give general conditions for asymptotic unbiasedness, and examples of when they are satisfied. (These conditions are model-dependent, and can be difficult to check.)

The rest of this paper is organized as follows. In Section 2, we review the current research literature on Bayesian nonparametric regression and highlight how the DP-GLM extends this field. In Section 3, we review Dirichlet process mixture models and generalized linear models. In Section 4, we construct the DP-GLM and derive algorithms for posterior computation. In Section 5 we give general conditions for unbiasedness and prove it in a specific case with conjugate priors. In Section 6 we compare DP-GLM and existing methods on three data sets. We illustrate that the DP-GLM provides a powerful nonparametric regression model that can accommodate many data analysis settings.

2 Related work

Gaussian process (GP), Bayesian regression trees and Dirichlet process mixtures are the most common prior choices for Bayesian nonparametric regression. GP priors assume that the observations arise from a Gaussian process model with known covariance function form (see Rasmussen and Williams (2006) for a review). Without modification, however, the GP model is only applicable to problems with continuous covariates and constant variance. The assumption of constant covariance can be eased by using Dirichlet process mixtures of GPs (Rasmussen and Ghahramani 2002) or

treed GPs (Gramacy and Lee 2008). Bayesian regression trees place a prior over the size of the tree and can be viewed as an automatic bandwidth selection method for classification and regression trees (CART) (Chipman et al. 1998). Bayesian trees have been expanded to include linear models (Chipman et al. 2002) and GPs (Gramacy and Lee 2008) in the leaf nodes.

In a regression setting, the Dirichlet process has been mainly used for problems with a continuous response. West et al. (1994), Escobar and West (1995) and Müller et al. (1996) used joint Gaussian mixtures for the covariates and response, and Rodriguez et al. (2009) generalized this method using dependent DPs for multiple response functionals. However, the method of Rodriguez et al. (2009) can be slow if a fully populated covariance matrix is used, and is potentially inaccurate if it is assumed diagonal. To avoid these issues—which amount to over-fitting the covariate distribution and under-fitting the response—some researchers have developed methods that use local weights on the covariates to produce local response DPs. This has been achieved with kernels and basis functions (Griffin and Steel 2007, Dunson et al. 2007), GPs (Gelfand et al. 2005) and general spatial-based weights (Griffin and Steel 2006, 2007, Duan et al. 2007). Still other methods, again based on dependent DPs, capture similarities between clusters, covariates or groups of outcomes, including in non-continuous settings (De Iorio et al. 2004, Rodriguez et al. 2009). The method presented here is equally applicable to the continuous response setting and tries to balance its fit of the covariate and response distributions by introducing local GLMs—the clustering structure is based on both the covariates and how the response varies with them.

There is somewhat less research that develops Bayesian nonparametric models for other types of response. Mukhopadhyay and Gelfand (1997) and Ibrahim and Kleinman (1998) used a DP prior for the random effects portion of a GLM. Likewise, Amewou-Atisso et al. (2003) used a DP prior to model arbitrary symmetric error distributions in a semi-parametric linear regression model. While these are powerful extensions of regression models, they still maintain the assumption that all covariates enter the model linearly in the same way. Our work is closest to Shahbaba and Neal (2009). They proposed a model that mixes over both the covariates and response, where the response is drawn from a multinomial logistic model. The DP-GLM studied here is a generalization of their idea.

Finally, asymptotic properties of Dirichlet process regression models have not been well studied. Most current literature centers around consistency of the posterior density for DP Gaussian mixture models (Barron et al. 1999, Ghosal et al. 1999, Ghosh and Ramamoorthi 2003, Walker 2004, Tokdar 2006) and semi-parametric linear regression models (Amewou-Atisso et al. 2003, Tokdar 2006). Only recently have the posterior properties of DP regression estimators been studied. Rodriguez et al. (2009) showed point-wise asymptotic unbiasedness for their model, which uses a dependent Dirichlet process prior, assuming continuous covariates under different treatments with a continuous responses and a conjugate base measure (normal-inverse Wishart). In Section 5 we show pointwise asymptotic unbiasedness of the DP-GLM in both the continuous and categorical response settings. In the continuous response setting, our results generalize those of Rodriguez et al. (2009) and Rodriguez (2007). Moreover in the categorical response setting, the same theoretical framework provides the same consistency results for the classification model of Shahbaba and Neal (2009).

3 Mathematical background

In this section we provide some mathematical background. We review Dirichlet process mixture models and generalized linear models.

Dirichlet Process Mixture Models. The *Dirichlet process* (DP) is a distribution over distributions (Ferguson 1973). It is denoted,

$$G \sim \text{DP}(\alpha G_0), \quad (2)$$

where G is a random distribution. There are two parameters. The base distribution G_0 is a distribution over the same space as G , e.g., if we want G to be a distribution on reals then G_0 must be a distribution on reals too. The concentration parameter α is a positive scalar. An important property of the DP is that random distributions G are discrete, and each places its mass on a countably infinite collection of atoms drawn from G_0 .

Consider the model

$$G \sim \text{DP}(\alpha, G_0) \quad (3)$$

$$\theta_i \sim G \quad (4)$$

The joint distribution of n replicates of θ_i is

$$p(\theta_{1:n} | \alpha, G_0) = \int \left(\prod_{i=1}^n G(\theta_i) \right) P(G) dG \quad (5)$$

One write this joint in a simpler form. Specifically, the conditional distribution of θ_n given $\theta_{1:(n-1)}$ follows a Polya urn distribution (Blackwell and MacQueen 1973),

$$\theta_n | \theta_{1:(n-1)} \sim \frac{1}{\alpha + n - 1} \sum_{i=1}^{n-1} \delta_{\theta_i} + \frac{\alpha}{\alpha + n - 1} G_0. \quad (6)$$

With the chain rule, this specifies the full joint distribution of $\theta_{1:n}$.

Equation (6) reveals the *clustering property* of the joint distribution of $\theta_{1:n}$: There is a positive probability that each θ_i will take on the value of another θ_j , leading some of the draws to share values. This equation also makes clear the roles of scaling parameter α and base distribution G_0 . The unique values contained in $\theta_{1:n}$ are drawn independently from G_0 and the parameter α determines how likely θ_{n+1} is to be a newly drawn value from G_0 rather than take on one of the values from $\theta_{1:n}$. The base measure G_0 controls the distribution of a newly drawn value.¹

In a DP mixture, θ is a latent parameter to an observed data point x (Antoniak 1974),

$$P \sim \text{DP}(\alpha G_0),$$

$$\Theta_i \sim P,$$

$$x_i | \theta_i \sim f(\cdot | \theta_i).$$

Examining the posterior distribution of $\theta_{1:n}$ given $x_{1:n}$ brings out its interpretation as an “infinite clustering” model. Because of the clustering property, observations are grouped by their shared parameters. Unlike finite clustering models, however, the number of groups is random and unknown. Moreover, a new data point can be assigned to a new cluster that was not previously seen in the data.

¹Technically, if G_0 is itself discrete then the “unique” values can themselves share values.

Generalized Linear Models. Generalized linear models (GLMs) build on linear regression to provide a flexible suite of predictive models. GLMs relate a linear model to a response via a link function; examples include familiar models like logistic regression, Poisson regression, and multinomial regression. See McCullagh and Nelder (1989) for a full discussion.

GLMs have three components: the conditional probability model for response Y , the linear predictor and the link function. The probability model for Y , dependent on covariates X , is

$$f(y|\eta) = \exp\left(\frac{y\eta - b(\eta)}{a(\phi)} + c(y, \phi)\right).$$

Here the canonical form of the exponential family is given, where a , b , and c are known functions specific to the exponential family, ϕ is an arbitrary scale (dispersion) parameter, and η is the canonical parameter. A linear predictor, $X\beta$, is used to determine the canonical parameter through a set of transformations. It can be shown that $b'(\eta) = \mu = \mathbb{E}[Y|X]$ (Brown 1986). However, we can choose a link function g such that $\mu = g^{-1}(X\beta)$, which defines η in terms of $X\beta$. The canonical form is useful for discussion of GLM properties, but we use the form parameterized by mean μ in the rest of this paper. GLMs are simple and flexible—they are an attractive choice for a local approximation of a global response function.

4 Dirichlet process mixtures of generalized linear models

We now turn to Dirichlet process mixtures of generalized linear models (DP-GLMs), a Bayesian predictive model that places prior mass on a large class of response densities. Given a data set of covariate-response pairs, we describe Gibbs sampling algorithms for approximate posterior inference and prediction. Theoretical properties of the DP-GLM are developed in Section 5.

4.1 Model formulation

In a DP-GLM, we assume that the covariates X are modeled by a mixture of exponential-family distributions, the response Y is modeled by a GLM conditioned on the inputs, and that these models are connected by associating a set of GLM coefficients with each exponential family mixture component. Let $\theta = (\theta_x, \theta_y)$ denote the bundle of parameters over X and $Y|X$, and let $\mathbb{G}_0$ denote a base measure on the space of both. For example, θ_x might be a set of d -dimensional multivariate Gaussian location and scale parameters for a vector of continuous covariates; θ_y might be a $d + 2$ -vector of reals for their corresponding GLM linear prediction coefficients, along with a GLM dispersion parameter. The full model is

$$\begin{aligned} P &\sim DP(\alpha\mathbb{G}_0), \\ \theta &= (\theta_{i,x}, \theta_{y,i}) | P \sim P, \\ X_i | \theta_{i,x} &\sim f_x(\cdot | \theta_{i,x}), \\ Y_i | x_i, \theta_{i,y} &\sim GLM(\cdot | X_i, \theta_{i,y}). \end{aligned}$$

The density f_x describes the covariate distribution; the GLM for y depends on the form of the response (continuous, count, category, or others) and how the response relates to the covariates (i.e., the link function).

The Dirichlet process clusters the covariate-response pairs (x, y) . When both are observed, i.e., in “training,” the posterior distribution of this model will cluster data points according to near-by covariates that exhibit the same kind of relationship to their response. When the response

Figure 1: The top figure shows the training data (gray) fitted into clusters, with the prediction given a single sample from the posterior, $\theta^{(i)}$ (red). The bottom figure shows the smoothed regression estimate (black) for the Gaussian model of Equation (7) with the testing data (blue). Data plot multipole moments against power spectrum C_ℓ for cosmic microwave background radiation (Bennett et al. 2003).

is not observed, its predictive expectation can be understood by clustering the covariates based on the training data, and then predicting the response according to the GLM associated with the covariates' cluster. The DP prior acts as a kernel for the covariates; instead of being a Euclidean metric, the DP measures the distance between two points by the probability that the hidden parameter is shared. See Figure 1 for a demonstration of the DP-GLM.

We now give a few examples of the DP-GLM that will be used throughout this paper.

Example: Gaussian Model. We now give an example of the DP-GLM for continuous covariates/response that will be used throughout the rest of the paper. For continuous covariates/response in $\mathbb{R}$, we model locally with a Gaussian distribution for the covariates and a linear regression model for the response. The covariates have mean $\mu_{i,j}$ and variance $\sigma_{i,j}^2$ for the j^{th} dimension of the i^{th} observation; the covariance matrix is diagonal for simplicity. The GLM parameters are the linear predictor $\beta_{i,0}, \dots, \beta_{i,d}$ and the response variance $\sigma_{i,y}^2$. Here, $\theta_{x,i} = (\mu_{i,1:d}, \sigma_{i,1:d})$ and $\theta_{y,i} = (\beta_{i,0:d}, \sigma_{i,y})$. This produces a mixture of multivariate Gaussians. The full model is,

$$\begin{aligned} P &\sim DP(\alpha \mathbb{G}_0), \\ \theta_i | P &\sim P, \\ X_{i,j} | \theta_{i,x} &\sim N(\mu_{ij}, \sigma_{ij}^2), & j = 1, \dots, d, \\ Y_i | X_i, \theta_{i,y} &\sim N\left(\beta_{i0} + \sum_{j=1}^d \beta_{ij} X_{ij}, \sigma_{iy}^2\right). \end{aligned} \tag{7}$$

Example: Multinomial Model (Shahbaba and Neal 2009). This model was proposed by Shahbaba and Neal (2009) for nonlinear classification, using a Gaussian mixture to model continuous covariates and a multinomial logistic model for a categorical response with K categories. The covariates have mean $\mu_{i,j}$ and variance $\sigma_{i,j}^2$ for the j^{th} dimension of the i^{th} observation; the covariance matrix is diagonal for simplicity. The GLM parameters are the K linear predictor $\beta_{i,0,k}, \dots, \beta_{i,d,k}$, $k = 1, \dots, K$. The full model is,

$$\begin{aligned} P &\sim DP(\alpha \mathbb{G}_0), \\ \theta_i | P &\sim P, \\ X_{i,j} | \theta_{i,x} &\sim N(\mu_{ij}, \sigma_{ij}^2), & j = 1, \dots, d, \\ \mathbb{P}(Y_i = k | X_i, \theta_{i,y}) &= \frac{\exp\left(\beta_{i,0,k} + \sum_{j=1}^d \beta_{i,j,k} X_{i,j}\right)}{\sum_{\ell=1}^K \exp\left(\beta_{i,0,\ell} + \sum_{j=1}^d \beta_{i,j,\ell} X_{i,j}\right)}, & k = 1, \dots, K. \end{aligned} \tag{8}$$

Example: Poisson Model with Categorical Covariates. The categorical covariates are modeled by a mixture of multinomial distributions and the count response by a Poisson distribution. If covariate j has K categories, let $(p_{i,j,1}, \dots, p_{i,j,K})$ be the probabilities for categories $1, \dots, K$. The covariates are then turned into indicator variables, $\mathbf{1}_{\{X_{i,j}=k\}}$, which are used with the linear

predictor, $\beta_i, 0, \beta_{i,1,1:K}, \dots, \beta_{i,d,1:K}$. The full model is,

$$\begin{aligned}
P &\sim DP(\alpha \mathbb{G}_0), \\
\theta_i | P &\sim P, \\
\mathbb{P}(X_{i,j} = k | \theta_{i,x}) &= p_{i,j,k}, \quad j = 1, \dots, d, \quad k = 1, \dots, K, \\
\lambda_i | X_i, \theta_{i,y} &= \exp \left(\beta_{i,0} + \sum_{j=1}^d \sum_{k=1}^K \beta_{i,j,k} \mathbf{1}_{\{X_{i,j}=k\}} \right), \\
\mathbb{P}(Y_i = k | X_i, \theta_{i,y}) &= \frac{e^{-\lambda_i} \lambda_i^k}{\ell!}, \quad k = 0, 1, 2, \dots
\end{aligned} \tag{9}$$

We apply Model (9) to data in Section 6.

4.2 Heteroscedasticity and overdispersion

One advantage of the DP-GLM is that it provides a strategy for handling common problems in predictive modeling. Many models, such as GLMs and Gaussian processes, make assumptions about data dispersion and homoscedasticity. Over-dispersion occurs in single parameter GLMs when the data variance is larger than the variance predicted by the model mean. Mukhopadhyay and Gelfand (1997) have successfully used DP mixtures over GLM intercept parameters to create classes of models that include over-dispersion. The DP-GLM retains this property, but is not limited to linearity in the covariates.

Homoscedasticity refers to the property of variance that is constant among all covariate regions; heteroscedasticity is variance that changes with the covariates. Models like GLMs and Gaussian processes assume homoscedasticity and can give poor fits when that assumption is violated. However, the DP-GLM can naturally accommodate heteroscedasticity when multiparameter GLMs are used, such as linear, gamma and negative binomial regression models. The mixture model setting allows the variance parameter to vary between clusters, creating smoothly transitioning heteroscedastic posterior response distributions.

A demonstration of this property is shown in Figure 2, where the DP-GLM is compared against a homoscedastic model, Gaussian processes, and heteroscedastic modifications of homoscedastic models, treed Gaussian processes and treed linear models. The DP-GLM is robust to heteroscedastic data—it provides a smooth mean function estimate, while the other models are not as robust or provide non-smooth estimates.

4.3 Posterior prediction with a DP-GLM

The DP-GLM is used in prediction problems. Given a collection of covariate-response pairs $D = (X_i, Y_i)_{i=1}^n$, our goal is to compute the expected response for a new set of covariates x , $\mathbb{E}[Y | x, D]$. We give the step-by-step process for formulating the model and forming the prediction.

Choosing the mixture component and GLM. We begin by choosing f_x and the GLM. The Dirichlet process mixture model and GLM provide flexibility both in terms of the covariates and the response. Dirichlet process mixture models allow nearly any type of variable to be modeled within the covariate mixture and subsequently transformed for use as a covariate in the GLM.

Note that certain mixture distributions simply support certain types of covariates but may not necessarily be a good fit. For example, one covariate might be strictly positive and continuous.

Figure 2: Modeling heteroscedasticity with the DP-GLM and other Bayesian nonparametric methods. The estimated mean function is given along with a 90% predicted confidence interval for the estimated underlying distribution. DP-GLM produces a smooth mean function and confidence interval.

This could be modeled with an exponential mixture,

$$X_i | \lambda_i \sim \text{Exp}(\lambda_i).$$

However, although exponential mixtures have support on $\mathbb{R}_{++}$, they are mixtures of a single parameter exponential family. This has implications for the variance of the distribution, which is determined by the mean of each component. Therefore, a mixture of gamma distributions or possibly even Gaussians would be a better fit. Both the gamma and Gaussian distributions have a mean and dispersion parameter, which free the mixture variance from the mean.

The GLM—for the conditional response—is chosen in much the same way.

Choosing the base measure and other hyperparameters. The choice of the base measure $\mathbb{G}_0$ affects how expressive the DP-GLM is, the computational efficiency of the prediction and whether some theoretical properties, such as asymptotic unbiasedness, hold. For example, $\mathbb{G}_0$ for the Gaussian model is a distribution over $(\mu_i, \sigma_i, \beta_{i,0:d}, \sigma_{i,y})$. A conjugate base measure is normal-inverse-gamma for each covariate dimension and multivariate normal inverse-gamma for the response parameters. This $\mathbb{G}_0$ allows all continuous, integrable distributions to be supported, retains theoretical properties, such as asymptotic unbiasedness, and yields highly efficient posterior sampling by allowing the Gibbs sampler to be collapsed (Neal 2000). However, this base measure is not expressive for small amounts of data. The tails quickly decline and the mean is tied to the variance. In summary, the base measure is often chosen in accordance to data size, distribution type, distribution features (heterogeneity, etc) and computational constraints.

Hyperparameters for the DP-GLM include the DP scaling parameter α and hyperparameters parameters for the base measure $\mathbb{G}_0$. It is often useful to place a gamma prior on α (Escobar and West 1995), while the parameters for $\mathbb{G}_0$ may have their own prior as well. Each level of priors reduces their influence but adds computational complexity (Escobar and West 1995).

Approximating the posterior and forming predictions. Our ultimate goal is to form a conditional expectation of the response, given a new set of covariates x and the observed data D , $\mathbb{E}[Y | X = x, D]$. Following the Bayesian regression methodology, we use iterated expectation, conditioning on the latent variables,

$$\mathbb{E}[Y | X = x, D] = \mathbb{E}[\mathbb{E}[Y | X = x, \theta_{1:n}] | D]. \quad (10)$$

The inner expectation is straight-forward to compute. Conditional on the latent parameters $\theta_{1:n}$ that generated the observed data, the expectation of the response is

$$\mathbb{E}[Y | X = x, \theta_{1:n}] = \frac{\alpha \int_{\mathcal{T}} \mathbb{E}[Y | X = x, \theta] f_x(x | \theta) \mathbb{G}_0(d\theta) + \sum_{i=1}^n \mathbb{E}[Y | X = x, \theta_i] f_x(x | \theta_i)}{\alpha \int_{\mathcal{T}} f_x(x | \theta) \mathbb{G}_0(d\theta) + \sum_{i=1}^n f_x(x | \theta_i)}. \quad (11)$$

Since Y is assumed to be a GLM, the quantity $\mathbb{E}[Y | X = x, \theta]$ is analytically available as a function of x and θ .

The outer expectation of Equation (10) is generally intractable. We approximate it by Monte Carlo integration using M posterior samples of $\theta_{1:n}$,

$$\mathbb{E}[Y | X = x, D] \approx \frac{1}{M} \sum_{m=1}^M \mathbb{E}[Y | X = x, \theta_{1:n}^{(m)}]. \quad (12)$$

The observations $\theta_{1:n}^{(m)}$ are i.i.d. from the posterior distribution of $\theta_{1:n} | D$.

We use Markov chain Monte Carlo (MCMC) to obtain M i.i.d. samples from this distribution. Specifically, we use Gibbs sampling, which is an effective algorithm for DP mixture models. (See Escobar (1994), MacEachern (1994), Escobar and West (1995) and MacEachern and Müller (1998) for foundational work; Neal (2000) provides a modern treatment and state of the art algorithms.) In short, we construct a Markov chain on the hidden variables $\theta_{1:n}$ such that its limiting distribution is the posterior of interest. Details for its implementation are given in Appendix A-1.

4.4 Comparison to the Dirichlet process mixture model regression

The DP-GLM directly models Y as being conditioned on X . Modeling the joint distribution of (x, y) as coming from a common mixture component in a classical DP mixture (see Section 3) also induces a conditional distribution of Y given X . In this Section, we conceptually compare these two approaches. (They are compared empirically in this section and Section 6.)

A generic Dirichlet process mixture model (DPMM) has the form,

$$\begin{aligned} P &\sim DP(\alpha \mathbb{G}_0), \\ \theta_i | P &\sim P, \\ X_i | \theta_{i,x} &\sim f_x(x | \theta_{i,x}), \\ Y_i | \theta_{i,y} &\sim f_y(y | \theta_{i,y}). \end{aligned} \tag{13}$$

DPMMs with this form have been studied for regression (Escobar and West 1995), but have generally not been used in practice due to poor results (with a diagonal covariance matrix) or computational difficulties (with a full covariance matrix). We focus on the former case, with diagonal covariance, to study why it has poor results and how the DP-GLM improves on these with a minimal increase in computational difficulty. The difference between Model (13) and the DP-GLM is that the distribution of Y given θ is conditionally independent of the covariates X . This is a small difference that has large consequences for the posterior distribution and predictive results.

Consider the log-likelihood of the posterior of the DPMM given in Model (13). Assume that f_y is a single parameter exponential, where $\theta_y = \beta$,

$$\ell(\theta^{dp} | D) \propto \sum_{i=1}^K \left[\ell(\beta_{C_i}) + \sum_{c \in C_i} \ell(y_c | \beta_{C_i}) + \sum_{j=1}^d \ell(\theta_{C_i, x_j} | D) \right]. \tag{14}$$

The log-likelihood of the DP-GLM posterior for a single parameter exponential family GLM, where $\theta_y = (\beta_0, \dots, \beta_d)$, has the form,

$$\ell(\theta^{dpglm} | D) \propto \sum_{i=1}^K \left[\sum_{j=0}^d \ell(\beta_{C_i, j}) + \sum_{c \in C_i} \ell(y_c | \beta_{C_i}^T x_c) + \sum_{j=1}^d \ell(\theta_{C_i, x_j} | D) \right]. \tag{15}$$

As the number of covariates grows, the likelihood associated with the covariates grows in both equations. However, the likelihood associated with the response also grows with the extra response parameters in Equation (15), whereas it is fixed in Equation (14).

These posterior differences lead to two predictive differences: 1) the DP-GLM is much more resistant to dimensionality than the DPMM, and 2) as the dimensionality grows, the DP-GLM produces less stable predictions than the DPMM. Since the number of response related parameters grows with the number of covariate dimensions in the DP-GLM, the relative posterior weight of the response does not shrink as quickly in the DP-GLM as it does in the DPMM. This keeps the

response variable relatively important in the selection of the mixture components and hence makes the DP-GLM a better predictor than the DPMM as the number of dimensions grows. However, each additional β_j adds some noise, so when d is large the DP-GLM estimate tends to be noisy.

While the additional GLM parameters help maintain the relevance of the response, they also add noise to the prediction. This can be seen in Figure 3. The GLM parameters in this figure have a Gaussian base measure, effectively creating a local ridge regression.² In lower dimensions, the DP-GLM produced more stable results than the DPMM because a smaller number of larger clusters were required to fit the data well. The DPMM, however, consistently produced stable results in higher dimensions as the response became more of a sample average than a local average. The DPMM has the potential to predict well if changes in the mean function coincide with underlying local modes of the covariate density. However, the DP-GLM forces the covariates into clusters that coincide more with the response variable due to the inclusion of the slope parameters.

We now discuss the theoretical properties of the DP-GLM.

5 Asymptotic Unbiasedness of the DP-GLM Regression Model

A desirable property of any estimator is that it should be unbiased, particularly in the limit. Diaconis and Freedman (1986) gives an example of a location model with a Dirichlet process prior where the estimated location can be bounded away from the true location, even when the number of observations approaches infinity. We want to assure that DP-GLM does not end up in a similar position.

Notation for this section is more complicated than the notation for the model. Let $f_0(x, y)$ be the true joint distribution of (x, y) ; in this case, we will assume that f_0 is a density. Let $\mathcal{F}$ be the set of all density functions over (x, y) . Let Π^f be the prior over $\mathcal{F}$ induced by the DP-GLM model. Let $\mathbb{E}_{f_0}[\cdot]$ denote the expectation under the true distribution and $\mathbb{E}_{\Pi^f}[\cdot]$ be the expectation under the prior Π^f .

In general, an estimator is a function of observations. Assuming a true distribution of those observations, an estimator is called unbiased if its expectation under that distribution is equal to the value that it estimates. In the case of DP-GLM, that would mean for every $x \in \mathcal{A}$ and every $n > 0$,

$$\mathbb{E}_{f_0} [\mathbb{E}_{\Pi} [Y|x, (X_i, Y_i)_{i=1}^n]] = \mathbb{E}_{f_0} [Y|x],$$

where $\mathcal{A}$ is some fixed domain, $\mathbb{E}_{\Pi}$ is the expectation with respect to the prior Π and $\mathbb{E}_{f_0}$ is the expectation with respect to the true distribution.

Since we use Bayesian priors in DP-GLM, we will have bias in almost all cases (Gelman et al. 2004). The best we can hope for is asymptotic unbiasedness, where as the number of observations grows to infinity, the mean function estimate converges to the true mean function. That is, for every $x \in \mathcal{A}$,

$$\mathbb{E}_{\Pi} [Y|x, (X_i, Y_i)_{i=1}^n] \rightarrow \mathbb{E} [Y|x] \quad \text{as } n \rightarrow \infty.$$

Diaconis and Freedman (1986) give an example for a location problem with a DP prior where the posterior estimate was not asymptotically unbiased. Extending that example, it follows that estimators with DP priors do not automatically receive asymptotic unbiasedness. We use consistency and uniform integrability to give conditions for asymptotic unbiasedness.

Consistency, the notion that as the number of observations goes to infinity the posterior distribution accumulates in neighborhoods arbitrarily “close” to the true distribution, is tightly related

²In unpublished results, we have also tried other sparsity-inducing base measures, such as a Laplacian distribution with an L1 penalty. They produced less stable results than the Gaussian base measure, likely due to the sample size differences between the clusters.

Figure 3: A plain Dirichlet process mixture model regression (left) versus DP-GLM, plotted against the number of spurious dimensions (vertical plots). The estimated mean function is given along with a 90% predicted confidence interval for the estimated underlying distribution. Data have one predictive covariate and a varying number of spurious covariates. The covariate data were generated by a mixture model. DP-GLM produces a smoother mean function and is much more resistant to spurious dimensionality.

to both asymptotic unbiasedness and mean function estimate existence. Weak consistency assures that the posterior distribution accumulates in regions of densities where “properly behaved” functions (i.e., bounded and continuous) integrated with respect to the densities in the region are arbitrarily close to the integral with respect to the true density. The expectation may not be bounded; in addition to weak consistency, uniform integrability is needed to guarantee that the posterior expectation converges to the true expectation, giving asymptotic unbiasedness. Uniform integrability also ensures that the posterior expectation almost surely exists with every additional observation. Therefore we need to show weak consistency and uniform integrability.

5.1 Asymptotic Unbiasedness

We approach asymptotic unbiasedness by showing weak consistency for the posterior of the *joint* distribution and then using uniform integrability to show that the conditional expectation $\mathbb{E}_{\Pi^n}[Y | X = x, (X_i, Y_i)_{i=1}^n]$ exists for every n and converges to the true expectation almost surely. The proof for this is a bit involved, so it has been placed in the Appendix.

Theorem 5.1. *Let x be in a compact set $\mathcal{C}$ and Π^f be a prior on $\mathcal{F}$. If,*

(i) for every $\delta > 0$, Π^f puts positive measure on

$$\left\{ f : \int f_0(x, y) \log \frac{f_0(x, y)}{f(x, y)} dx dy < \delta \right\},$$

(ii) $\int |y| f_0(y|x) dy < \infty$ for every $x \in \mathcal{C}$, and

(iii) there exists an $\epsilon > 0$ such that for every $x \in \mathcal{C}$,

$$\int \int |y|^{1+\epsilon} f_y(y|x, \theta) \mathbb{G}_0(d\theta) < \infty,$$

then for every $n \geq 0$, $\mathbb{E}_{\Pi}[Y|x, (X_i, Y_i)_{1:n}]$ exists and has the limit $\mathbb{E}_{f_0}[Y|X = x]$, almost surely with respect to the observation product measure, $\mathbb{P}_{f_0^\infty}$.

The conditions of Theorem 5.1 must be checked for the problem (f_0) and prior (Π^f) pair, and can be difficult to show. Condition (i) assures weak consistency of the posterior, condition (ii) guarantees a mean function exists in the limit and condition (iii) guarantees that positive probability is only placed on densities that yield a finite mean function estimate, which is used for uniform integrability. Condition (i) is quite hard to show, but there has been recent work demonstrating weak consistency for a number of Dirichlet process mixture models and priors (Ghosal et al. 1999, Ghosh and Ramamoorthi 2003, Amewou-Atisso et al. 2003, Tokdar 2006). See the Appendix A-2 for a proof of Theorem 5.1.

5.2 Asymptotic Unbiasedness Example: Gaussian Model

Theorem 5.2 gives conditions for when Theorem 5.1 holds for the Gaussian model. We will then give some examples of when Theorem 5.2 holds.

Theorem 5.2. *Suppose that:*

(i) $f_0(x, y)$ is absolutely continuous with respect to $\mathbb{R}^{d+1}$ and has compact support,

(ii) all location-scale-slope parameter mixtures are in the weak support of $\mathbb{G}_0$, and

(iii) $\mathbb{G}_0$ satisfies assumption (iii) of Theorem 5.1.

Then, the conclusions of Theorem 5.1 hold.

See the Appendix A-3 for the proof. Examples that satisfy Theorem 5.2 are as follows, with technical results in the Appendix.

Normal-Inverse-Wishart. Note that in the Gaussian case, slope parameters can be generated by a full covariance matrix: using a conjugate prior, a Normal-Inverse-Wishart, will produce an instance of the DP-GLM. Define the following model, which was used by Müller et al. (1996),

$$\begin{aligned} P &\sim DP(\alpha \mathbb{G}_0), \\ \theta_i | P &\sim P, \\ (X_i, Y_i) | \theta_i &\sim N(\mu, \Sigma). \end{aligned} \tag{16}$$

The last line of Model (16) can be broken down in the following manner,

$$\begin{aligned} X_i | \theta_i &\sim N(\mu_x, \Sigma_x), \\ Y_i | \theta_i &\sim N(\mu_y + b^T \Sigma_x^{-1} b (X_i - \mu_x), \sigma_y^2 - b^T \Sigma_x^{-1} b), \end{aligned}$$

where

$$\mu = \begin{bmatrix} \mu_y \\ \mu_x \end{bmatrix}, \quad \Sigma = \begin{bmatrix} \sigma_y^2 & b^T \\ b & \Sigma_x \end{bmatrix}.$$

We can then define β as,

$$\beta_0 = \mu_y - b^T \Sigma_x^{-1} \mu_x, \quad \beta_{1:d} = b^T \Sigma_x^{-1}.$$

The base measure $\mathbb{G}_0$ is defined as,

$$(\mu, \Sigma) \sim \text{Normal Inverse Wishart}(\lambda, \nu, a, B).$$

Here λ is a mean vector, ν is a scaling parameter for the mean, a is a scaling parameter for the covariance, and B is a covariance matrix.

Diagonal Normal-Inverse-Gamma. It is often more computationally efficient to specify that Σ_x is a diagonal matrix. In this case, we can specify a conjugate base measure component by component:

$$\begin{aligned} \sigma_{i,j} &\sim \text{Inverse Gamma}(a_j, b_j), & j = 1, \dots, d, \\ \mu_{i,j} | \sigma_{i,j} &\sim N(\lambda_j, \sigma_{i,j} / \nu_j), & j = 1, \dots, d, \\ \sigma_{i,y} &\sim \text{Inverse Gamma}(a_y, b_y), \\ \beta_{i,j} | \sigma_{i,y} &\sim N_{d+1}(\lambda_y, \sigma_y / \nu_y). \end{aligned}$$

The Gibbs sampler can still be collapsed, but the computational cost is much lower than the full Normal-Inverse-Wishart.

Normal Mean, Log Normal Variance. Conjugate base measures tie the mean to the variance and can be a poor fit for small, heteroscedastic data sets. The following base measure was proposed Shahbaba and Neal (2009),

$$\begin{aligned}\log(\sigma_{i,j}) &\sim N(m_{j,\sigma}, s_{j,\sigma}^2), & j = y, 1, \dots, d, \\ \mu_{i,j} &\sim N(m_{j,\mu}, s_{j,\mu}^2), & j = 1, \dots, d, \\ \beta_{i,j} &\sim N(m_{j,\beta}, s_{j,\beta}^2) & j = 0, \dots, d.\end{aligned}$$

5.3 Asymptotic Unbiasedness Example: Multinomial Model

Now consider the multinomial model of Shahbaba and Neal (2009), given in Model (8),

$$\begin{aligned}P &\sim DP(\alpha \mathbb{G}_0), \\ \theta_i | P &\sim P, \\ X_{i,j} | \theta_{i,x} &\sim N(\mu_{ij}, \sigma_{ij}^2), & j = 1, \dots, d, \\ \mathbb{P}(Y_i = k | X_i, \theta_{i,y}) &= \frac{\exp\left(\beta_{i,0,k} + \sum_{j=1}^d \beta_{i,j,k} X_{i,j}\right)}{\sum_{\ell=1}^K \exp\left(\beta_{i,0,\ell} + \sum_{j=1}^d \beta_{i,j,\ell} X_{i,j}\right)}, & k = 1, \dots, K\end{aligned}$$

Theorem 5.3 gives conditions for when Theorem 5.1 holds for the Multinomial model. We will then given some examples of when Theorem 5.3 holds.

Theorem 5.3. *Suppose that:*

- (i) $f_0(x)$ is absolutely continuous with respect to $\mathbb{R}^d$ and has compact support,
- (ii) $\mathbb{P}(Y = k | x)$ is continuous in x for every $x \in \mathcal{C}$ and $k = 1, \dots, K$,
- (iii) all location-scale-slope parameter mixtures are in the weak support of $\mathbb{G}_0$, and
- (iv) $\mathbb{G}_0$ satisfies assumption (iii) of Theorem 5.1.

Then, the conclusions of Theorem 5.1 hold.

See Appendix A-4 for the proof. We now give some examples of base measures that satisfy Theorem 5.3. In general, the base measure for the continuous covariates is the same as those in the Gaussian model, while the GLM parameters are given a Gaussian base measure. Technical results are discussed in the Appendix A-4.

Normal-Inverse-Wishart. The covariates have a Normal-Inverse-Wishart base measure while the GLM parameters have a Gaussian base measure,

$$\begin{aligned}(\mu_{i,x}, \Sigma_{i,x}) &\sim \text{Normal Inverse Wishart}(\lambda, \nu, a, B), \\ \beta_{i,j,k} &\sim N(m_{j,k}, s_{j,k}^2), & j = 0, \dots, d, \quad k = 1, \dots, K.\end{aligned}$$

Diagonal Normal-Inverse-Gamma. It is often more computationally efficient to specify that Σ_x is a diagonal matrix. Again, we can specify a conjugate base measure component by component while keeping the Gaussian base measure on the GLM components,

$$\begin{aligned}\sigma_{i,j} &\sim \text{Inverse Gamma}(a_j, b_j), & j = 1, \dots, d, \\ \mu_{i,j} | \sigma_{i,j} &\sim N(\lambda_j, \sigma_{i,j} / \nu_j), & j = 1, \dots, d, \\ \beta_{i,j,k} | \sigma_{i,y} &\sim N(m_{j,k}, s_{j,k}^2), & j = 0, \dots, d, \quad k = 1, \dots, K.\end{aligned}$$

Normal Mean, Log Normal Variance. Likewise, for heteroscedastic covariates we can use the log normal base measure of Shahbaba and Neal (2009),

$$\begin{aligned} \log(\sigma_{i,j}) &\sim N(m_{j,\sigma}, s_{j,\sigma}^2), & j = 1, \dots, d, \\ \mu_{i,j} &\sim N(m_{j,\mu}, s_{j,\mu}^2), & j = 1, \dots, d, \\ \beta_{i,j,k} &\sim N(m_{j,k,\beta}, s_{j,k,\beta}^2) & j = 0, \dots, d, \quad k = 1, \dots, K. \end{aligned}$$

6 Empirical study

We compare the performance of DP-GLM regression to other regression methods. We studied data sets that illustrate the strengths of the DP-GLM, including robustness with respect to data type, heteroscedasticity and higher dimensionality than can be approached with traditional methods. Shahbaba and Neal (2009) used a similar model on data with categorical covariates and count responses; their numerical results were encouraging. We tested the DP-GLM on the following datasets.

Datasets. We selected three data sets with continuous response variables. They highlight various data difficulties within regression, such as error heteroscedasticity, moderate dimensionality (10–12 covariates), various input types and response types.

- **Cosmic Microwave Background (CMB) Bennett et al. (2003).** The data set consists of 899 observations which map positive integers $\ell = 1, 2, \dots, 899$, called ‘multipole moments,’ to the power spectrum C_ℓ . Both the covariate and response are considered continuous. The data pose challenges because they are highly nonlinear and heteroscedastic. Since this data set is only two dimensions, it allows us to easily demonstrate how the various methods approach estimating a mean function while dealing with non-linearity and heteroscedasticity.
- **Concrete Compressive Strength (CCS) Yeh (1998).** The data set has eight covariates: the components cement, blast furnace slag, fly ash, water, superplasticizer, coarse aggregate and fine aggregate, all measured in kg per m^3 , and the age of the mixture in days; all are continuous. The response is the compressive strength of the resulting concrete, also continuous. There are 1,030 observations. The data have relatively little noise. Difficulties arise from the moderate dimensionality of the data.
- **Solar Flare (Solar) Bradshaw (1989).** The response is the number of solar flares in a 24 hour period in a given area; there are 11 categorical covariates. 7 covariates are binary and 4 have 3 to 6 classes for a total of 22 categories. The response is the sum of all types of solar flares for the area. There are 1,389 observations. Difficulties are created by the moderately high dimensionality, categorical covariates and count response. Few regression methods can appropriately model this data.

Dataset testing sizes ranged from very small (20 observations) to moderate sized (800 observations). Small dataset sizes were included due to interests in (future) online applications.

Competitors. The competitors represent a variety of regression methods; some methods are only suitable for certain types of regression problems.

- **Ordinary Least Squares (OLS).** A parametric method that often provides a reasonable fit when there are few observations. Although OLS can be extended for use with any set

of basis functions, finding basis functions that span the true function is a difficult task. We naively choose $[1 X_1 \dots X_d]^T$ as basis functions. OLS can be modified to accommodate both continuous and categorical inputs, but it requires a continuous response function.

- **CART.** A nonparametric tree regression method generated by the Matlab function `classregtree`. It accommodates both continuous and categorical inputs and any type of response.
- **Bayesian CART.** A tree regression model with a prior over tree size (Chipman et al. 1998); it was implemented in R with the `tgp` package.
- **Bayesian Treed Linear Model.** A tree regression model with a prior over tree size and a linear model in each of the leaves (Chipman et al. 2002); it was implemented in R with the `tgp` package.
- **Gaussian Processes (GP).** A nonparametric method that can accommodate only continuous inputs and continuous responses. GPs were generated in Matlab by the program `gpr` of Rasmussen and Williams (2006). It is suitable only for continuous responses and covariates.
- **Treed Gaussian Processes.** A tree regression model with a prior over tree size and a GP on each leaf node (Gramacy and Lee 2008); it was implemented in R with the `tgp` package.
- **Basic DP Regression.** Similar to DP-GLM, except the response is a function only of μ_y , rather than $\beta_0 + \sum \beta_i x_i$. For the Gaussian model,

$$\begin{aligned} P &\sim DP(\alpha \mathbb{G}_0), \\ \theta_i | P &\sim P, \\ X_i | \theta_i &\sim N(\mu_{i,x}, \sigma_{i,x}^2), \\ Y_i | \theta_i &\sim N(\mu_{i,y}, \sigma_{i,y}^2). \end{aligned}$$

This model was explored in Section 4.4.

- **Poisson GLM (GLM).** A Poisson generalized linear model, used on the Solar Flare data set. It is suitable for count responses.

Cosmic Microwave Background (CMB) Results. For this dataset, we used a Gaussian model with base measure

$$\begin{aligned} \mu_x &\sim N(m_x, s_x^2), & \sigma_x^2 &\sim \exp \{ N(m_{x,s}, s_{x,s}^2) \}, \\ \beta_{0:d} &\sim N(m_{y,0:d}, s_{y,0:d}^2), & \sigma_y^2 &\sim \exp \{ N(m_{x,s}, s_{x,s}^2) \}. \end{aligned}$$

This prior was chosen because the variance tails are heavier than an inverse gamma and the mean is not tied to the variance. It is a good choice for heterogeneous data because of those features. Computational details are given in Appendix A-5.

All non-linear methods except for CART (DP-GLM, Bayesian CART, treed linear models, GPs and treed GPs) did comparably on this dataset; CART had difficulty finding an appropriate bandwidth. Linear regression did poorly due to the non-linearity of the dataset. Fits for heteroscedasticity for the DP-GLM, GPs, treed GPs and treed linear models on 250 training data points can be seen in Figure 2. See Figure 4 and Table 1 for results.

Figure 4: The average mean absolute error (top) and mean squared error (bottom) for ordinary least squares (OLS), tree regression, Gaussian processes and DP-GLM on the CMB data set. The data were normalized. Mean $\pm$ one standard deviation are given for each method.

METHOD <i>Training set size</i>	MEAN ABSOLUTE ERROR					MEAN SQUARE ERROR

GAUSSIAN PROCESS	0.55	0.53	0.50	0.51	0.47	1.06	0.97	0.93	0.96	0.85
TREED GP	0.52	0.49	0.48	0.48	0.46	1.03	0.95	0.95	0.96	0.89

Table 1: Mean absolute and square errors for methods on the CMB data set by training data size. The best results for each size of training data are in bold.

Figure 5: The average mean absolute error (top) and mean squared error (bottom) for ordinary least squares (OLS), tree regression, Gaussian processes, location/scale DP and the DP-GLM Poisson model on the CCS data set. The data were normalized. Mean $\pm$ one standard deviation are given for each method.

Concrete Compressive Strength (CCS) Results. The CCS dataset was chosen because of its moderately high dimensionality and continuous covariates and response. For this dataset, we used a Gaussian model and a conjugate base measure with conditionally independent covariate and response parameters,

$$(\mu_x, \sigma_x^2) \sim \text{Normal} - \text{Inverse} - \text{Gamma}(m_x, s_x, a_x, b_x),$$

$$(\beta_{0:d}, \sigma_y^2) \sim \text{Multivariate Normal} - \text{Inverse} - \text{Gamma}(M_y, S_y, a_y, b_y).$$

This base measure allows the sampler to be fully collapsed but has fewer covariate-associated parameters than a full Normal-Inverse-Wishart base measure, giving it a better fit in a moderate dimensional setting. In testing, it also provided better results for this dataset than the exponentiated Normal base measure used for the CMB dataset; this is likely due to the low noise and variance of the CCS dataset. Computational details are given in Appendix A-6.

Results on this dataset were more varied than those for the CMB dataset. GPs had the best performance overall; on smaller sets of training data, the DP-GLM outperformed frequentist CART. Linear regression, basic DP regression and Bayesian CART all performed comparatively poorly. Treed linear models and treed GPs performed very well most of the time, but had convergence problems leading to overall higher levels of predictive error. Convergence issues were likely caused by the moderate dimensionality (8 covariates) of the dataset. See Figure 5 and Table 2 for results.

Table 3: Mean absolute and square errors for methods on the Solar data set by training data size. The best results for each size of training data are in bold.

Solar Flare Results. The Solar dataset was chosen to demonstrate the flexibility of DP-GLM. Many regression techniques cannot accommodate categorical covariates and most cannot accommodate a count-type response. For this dataset, we used the following DP-GLM,

$$\begin{aligned}
P &\sim DP(\alpha \mathbb{G}_0), \\
\theta_i &| P \sim P, \\
X_{i,j} &| \theta_i \sim (p_{i,j,1}, \dots, p_{i,j,K(j)}), \\
Y_i &| \theta_i \sim \text{Poisson} \left(\beta_{i,0} + \sum_{j=1}^d \sum_{k=1}^{K(j)} \beta_{i,j,k} \mathbf{1}_{\{X_{i,j}=k\}} \right).
\end{aligned}$$

We used a conjugate covariate base measure and a Gaussian base measure for β ,

$$(p_{j,1}, \dots, p_{j,K(j)}) \sim \text{Dirichlet}(a_{j,1}, \dots, a_{j,K(j)}), \quad \beta_{j,k} \sim N(m_{j,k}, s_{j,k}^2).$$

Computational details are given in Appendix A-7.

The only other methods that can handle this dataset are CART, Bayesian CART and Poisson regression. The DP-GLM had the best performance under both error measures (with Bayesian CART a close second). The high mean squared error values suggests that frequentist CART overfit while the high mean absolute error for Poisson regression suggests that it did not adequately fit nonlinearities. See Figure 6 and Table 3 for results.

Discussion. The DP-GLM is a relatively strong competitor on all of the datasets, but only CART and Bayesian CART match its flexibility. It was more stable than most of its Bayesian competitors (aside from GPs) on the CCS dataset. Our results suggest that the DP-GLM would be a good

Figure 6: The average mean absolute error (top) and mean squared error (bottom) for tree regression, a Poisson GLM (GLM) and DP-GLM on the Solar data set. Mean $\pm$ one standard deviation are given for each method.

choice for small sample sizes when there is significant prior knowledge; in those cases, it acts as an automatic outlier detector and produces a result that is similar to a Bayesian GLM. Results from Section 4 suggest that the DP-GLM is not appropriate for problems with high dimensional covariates; in those cases, the covariate posterior swamps the response posterior with poor numerical results.

7 Conclusions and Future Work

We developed the Dirichlet process mixture of generalized linear models (DP-GLM), a flexible Bayesian regression technique. We discussed its statistical and empirical properties; we gave conditions for asymptotic unbiasedness and gave situations in which they hold; finally, we tested the DP-GLM on a variety of datasets against state of the art Bayesian competitors. The DP-GLM was competitive in most setting and provided stable, conservative estimates, even with extremely small sample sizes.

One concern with the DP-GLM is computational efficiency as implemented. All results were generated using MCMC, which does not scale well to large datasets. An alternative implementation using variational inference (Blei and Jordan 2005), possibly online variational inference (Sato 2001), would greatly increase computational feasibility for large datasets.

Our empirical analysis of the DP-GLM has implications for regression methods that rely on modeling a joint posterior distribution of the covariates and the response. Our experiments suggest that the covariate posterior can swamp the response posterior, but careful modeling can mitigate the effects for problems with low to moderate dimensionality. A better understanding would allow us to know when and how such modeling problems can be avoided.

Appendix

A-1 Posterior Inference

In the Gibbs sampler, the state is the collection of labels $(z_1, \dots, z_n)$ and parameters $(\theta_1^*, \dots, \theta_K^*)$, where θ_c^* is the parameter associated with cluster c and K is the number of unique labels given $z_{1:n}$. In a collapsed Gibbs sampler, all or part of $(\theta_1^*, \dots, \theta_K^*)$ is eliminated through integration. Let $z_{-i} = (z_1, \dots, z_{i-1}, z_{i+1}, \dots, z_n)$. A basic inference algorithm is given in Algorithm 1. Convergence

Algorithm 1: Gibbs Sampling Algorithm for the DP-GLM

Require: Starting state $(z_1, \dots, z_n)$, $(\theta_1^*, \dots, \theta_K^*)$, convergence criteria.

```

1: repeat
2:   for  $i = 1$  to  $n$  do
3:     Sample  $z_i$  from  $p(z_i \mid D, z_{-i}, \theta_{1:K}^*)$ .
4:   end for
5:   for  $c = 1$  to  $K$  do
6:     Sample  $\theta_c^*$  given  $\{(X_i, Y_i) : z_i = c\}$ .
7:   end for
8:   if Convergence criteria are met then

10:  end if
11: until  $M$  posterior samples obtained.
```

criteria for our numerical examples are given in Appendix sections A-5 to A-7. See Gelman et al. (2004) for a more complete discussion on convergence criteria.

We can sample from the distribution $p(z_i | D, z_{-i}, \theta_{1:K}^*)$ as follows,

$$p(z_i | D, z_{-i}, \theta_{1:K}^*) \propto p(z_i | z_{-i})p(X_i | z_{1:n}, D, \theta_{1:K}^*)p(Y_i | X_i, z_{1:n}, D, \theta_{1:K}^*). \quad (\text{A-1})$$

The first part of Equation (A-1) is the Chinese Restaurant Process posterior value,

$$p(z_i | z_{-i}) = \begin{cases} \frac{n_{z_j}}{n-1+\alpha} & \text{if } z_i = z_j \text{ for some } j \neq i, \\ \frac{\alpha}{n-1+\alpha} & \text{if } z_i \neq z_j \text{ for all } j \neq i. \end{cases}$$

Here n_{z_j} is the number of elements with the label z_j . The second term of Equation (A-1) is the same as in other Gibbs sampling algorithms. If possible, the component parameters $\theta_{1:K}^*$ can be integrated out (in the case of conjugate base measures and parameters that pertain strictly to the covariates) and $p(X_i | z_{1:n}, D, \theta_{1:K}^*)$ can be replaced with

$$\int p(X_i | z_{1:n}, D, \theta_{1:K}^*)p(\theta_{1:K}^* | z_{1:n})d\theta_{1:K}^*.$$

The third term of Equation (A-1) is not found in traditional Dirichlet process mixture model samplers. In some cases, this term can also be collapsed, such as Gaussian model with a Normal-Inverse-Gamma base measure. In that case,

$$\begin{aligned} p(Y_i | X_i, z_c, D_c) &= \frac{\Gamma((n_n + 1)/2)}{\Gamma(n_n/2)} (n_n s_n)^{-1/2} \exp \left(-1/2(n_n + 1) \log \left(1 + \frac{1}{n_n s_n} (Y_i - m_n)^2 \right) \right), \\ \tilde{V} &= \left(V^{-1} + \tilde{X}_c^T \tilde{X}_c \right)^{-1}, \\ \hat{m}_n &= \tilde{V} \left(m_0 V^{-1} + \tilde{X}_c^T Y_c \right) \\ m_n &= \tilde{X}_i \hat{m}_n, \\ n_n &= n_{y0} + n_c, \\ s_n^2 &= 4 \left(s_{y0}^2 + 1/2 \left(m_0 V^{-1} m_0^T + Y_c^T Y_c - \hat{m}_n^T \tilde{V}^{-1} \hat{m}_n \right) \right) / \left((n_{y0} + n_c) \tilde{X}_c \tilde{V} \tilde{X}_c^T \right) \end{aligned}$$

Here, we define $\tilde{X}_c = \{[1X_j] : z_j = z_c\}$, $Y_c = \{Y_j : z_j = z_c\}$, $\tilde{X}_i = [1X_i]$, n_c is the number of data associated with label z_c and the base measure is define as,

$$\begin{aligned} \sigma_y^2 &\sim \text{Inverse} - \text{Gamma}(n_{y0}, s_{y0}^2), \\ \beta | \sigma_y^2 &\sim N(m_0, \sigma_y^2 V). \end{aligned}$$

A-2 Proof of Theorem 5.1

The outline for the proof of Theorem 5.1 is as follows:

- 1) Show consistency under the set of conditions given in part (i) of Theorem 5.1.
- 2) Show that consistency and conditions (ii) and (iii) imply the existence and convergence of the expectation.
 - a) Show that weak consistency implies pointwise convergence of the conditional density.
 - b) Note that pointwise convergence of the conditional density implies convergence of the conditional expectation.

The first part of the proof relies on a theorem by Schwartz (1965).

Theorem A-1 (Schwartz (1965)). *Let Π^f be a prior on $\mathcal{F}$. Then, if Π^f places positive probability on all neighborhoods*

$$\left\{ f : \int f_0(x, y) \log \frac{f_0(x, y)}{f(x, y)} dx dy < \delta \right\}$$

for every $\delta > 0$, then Π^f is weakly consistent at f_0 .

Therefore, consistency of the posterior at f_0 follows directly from condition (i).

We now show pointwise convergence of the conditional densities. Let $f_n(x, y)$ be the Bayes estimate of the density under Π^f after n observations,

$$f_n(x, y) = \int_{\mathcal{F}} f(x, y) \Pi^f(df | (X_i, Y_i)_{i=1}^n).$$

Posterior consistency of Π^f at f_0 implies that $f_n(x, y)$ converges weakly to $f_0(x, y)$, pointwise in (x, y) .

Lemma A-2. *Suppose that Π^f is weakly consistent at f_0 . Then $f_n(y|x)$ converges weakly to $f_0(y|x)$.*

Proof. If Π^f is weakly consistent at f_0 , then $f_n(x, y)$ converges weakly to $f_0(x, y)$. We can integrate out y to see that $f_n(x)$ also converges weakly to $f_0(x)$. Then note that

$$\lim_{n \rightarrow \infty} f_n(y|x) = \lim_{n \rightarrow \infty} \frac{f_n(x, y)}{f_n(x)} = \frac{f_0(x, y)}{f_0(x)} = f_0(y|x).$$

□

Now we are ready to prove Theorem 5.1.

Theorem 5.1. Existence of expectations: by condition (iii) of Theorem 5.1,

$$\int |y|^{1+\epsilon} f_n(y|x) dy < \infty$$

almost surely. This and condition (ii) ensure uniform integrability and that $\mathbb{E}_{\Pi^f}[Y | X = x, (X_i, Y_i)_{i=1}^n]$ exists for every n almost surely. By Lemma A-2, the conditional density converges weakly to the true conditional density; weak convergence and uniform integrability ensure that the expectations converge: $\mathbb{E}_{\Pi^f}[Y | X = x, (X_i, Y_i)_{i=1}^n]$ converges pointwise in x to $\mathbb{E}_{f_0}[Y | X = x]$.

□

A-3 Proof of Theorem 5.2 and Results for Base Measures

We sketch the proof of this theorem in two parts. First, we show that we can use a Gaussian convolution approximation to $f_0(x, y)$, and second that the posterior of the convolution is weakly consistent at f_0 . We do this only for the case where x is a scalar, but it can be easily extended to the vector case.

Uniform equicontinuity will be used throughout this proof and the next.

Definition A-3. *A set of functions $\mathcal{F}$ is uniformly equicontinuous if for every $\epsilon > 0$, there exists a $\delta > 0$ such that for every $x_1, x_2 \in \mathcal{X}$, if $\|x_1 - x_2\| < \delta$, then $|f(x_1) - f(x_2)| < \epsilon$ for all $f \in \mathcal{F}$.*

Theorem A-4. Suppose that $f_0(x, y)$ has compact support; that is, there exists some x' and y' such that $f_0(x, y) = 0$ whenever $(x, y) \notin [-x', x'] \times [-y', y']$. Set

$$f_{0,h}(x, y) = \int \int \int f_0(\mu, \beta_0, \beta_1) \phi_{h_x}(x - \mu) \phi_{h_y}(y - \beta_0 - \beta_1 \mu) d\mu d\beta_0 d\beta_1,$$

where $\phi_h(x)$ is the Gaussian pdf with variance h , evaluated at x . Then

$$\lim_{h_x, h_y \rightarrow 0} \int \int f_0(x, y) \log \frac{f_0(x, y)}{f_{0,h}(x, y)} dx dy = 0.$$

Proof. This proof follows Remark 3 of Ghosal et al. (1999) closely. Fix $0 < c_1 \leq c_2$. Because f_0 is compactly supported, there exists $a' < b'$, $a'' < b''$, and $a''' < b'''$ such that for every

$$(\mu, \beta_0, \beta_1) \in [a', b'] \times [a'', b''] \times [a''', b'''] = \mathcal{D},$$

$$f_0(\mu, \beta_0 + \beta_1 \mu) > c_1 \text{ and}$$

$$(\mu, \beta_0, \beta_1) \notin \mathcal{D},$$

$f_0(\mu, \beta_0 + \beta_1 \mu) < c_2$. We can choose $h_{0,x}, h_{0,y}$ such that $N(0, h_{0,x})$ gives $1/3$ probability to $(0, b' - a')$. Define

$$\begin{aligned} d_1 &= \max_{\beta_0 \in [a'', b''], \beta_1 \in [a''', b''']} (\beta_0 + \beta_1 a'), & d_2 &= \min_{\beta_0 \in [a'', b''], \beta_1 \in [a''', b''']} (\beta_0 + \beta_1 b'), \\ d'_1 &= \min_{\beta_0 \in [a'', b''], \beta_1 \in [a''', b''']} (\beta_0 + \beta_1 a'), & d'_2 &= \max_{\beta_0 \in [a'', b''], \beta_1 \in [a''', b''']} (\beta_0 + \beta_1 b'). \end{aligned}$$

By choice of c_1, c_2 , we can ensure that $d_1 < d_2$. We can choose $h_{0,y}$ such that $N(0, h_{0,y})$ gives $1/3$ probability to $(0, d'_2 - d'_1)$. Then we compute lower bounds on the convolutions for each part of our partitioned space. Let $h_x < h_{0,x}$ and $h_y < h_{0,y}$. If $(x, y) \in [a', b'] \times [d'_1, d'_2]$,

$$\begin{aligned} f_{0,h}(x, y) &\geq \int_{a'}^{b'} \int_{a''}^{b''} \int_{a'''}^{b'''} f_0(\mu, \beta_0 + \beta_1 \mu) \phi_{h_x}(x - \mu) \phi_{h_y}(y - \beta_0 - \beta_1 \mu) d\mu d\beta_0 d\beta_1 \\ &\geq c_1 (\Phi((b' - x)/h_x) + \Phi((x - a')/h_x)) (\Phi((y - d_1)/h_y) + \Phi((d_2 - y)/h_y)) \\ &\geq c_1/9. \end{aligned}$$

Now consider $(x, y) \in [a', b'] \times [d'_2, \infty)$,

$$\begin{aligned} f_{0,h}(x, y) &\geq \int_{a'}^{b'} \int_{a''}^y \int_{a'''}^y f_0(\mu, \beta_0 + \beta_1 \mu) \phi_{h_x}(x - \mu) \phi_{h_y}(y - \beta_0 - \beta_1 \mu) d\mu d\beta_0 d\beta_1 \\ &\geq f_0(x, y) (\Phi((b' - x)/h_x) + \Phi((x - a')/h_x)) (1/2 + \Phi((d'_2 - d'_1)/h_y) - 1) \\ &\geq f_0(x, y)/9. \end{aligned}$$

The negative tail and both cases where $x \notin [a', b'], y \in [d'_1, d'_2]$ can be bounded in the same manner. Now consider $(x, y) \in [b', \infty) \times [d'_2, \infty)$,

$$\begin{aligned} f_{0,h}(x, y) &\geq \int_{a'}^x \int_{a''}^y \int_{a'''}^y f_0(\mu, \beta_0 + \beta_1 \mu) \phi_{h_x}(x - \mu) \phi_{h_y}(y - \beta_0 - \beta_1 \mu) d\mu d\beta_0 d\beta_1 \\ &\geq f_0(x, y) (1/2 + \Phi((b' - a')/h_x) - 1) (1/2 + \Phi((d'_2 - d'_1)/h_y) - 1) \\ &\geq f_0(x, y)/9. \end{aligned}$$

We can do this for the other three regions to generate the function,

$$g(x, y) = \begin{cases} \log(3f_0(x, y)/c_1) & \text{if } x, y \in [a', b'] \times [d'_1, d'_2], \\ \log(9) & \text{otherwise.} \end{cases}$$

The function $g(x, y)$ dominates $\log(f_0/f_{0,h})$ and is $\mathbb{P}_{f_0}$ integrable. Using dominated convergence and a variant of Fatou's lemma, $\int f_0 \log(f_0/f_{0,h}) \rightarrow 0$ as $h_x, h_y \rightarrow 0$. $\square$

Theorem A-5. Define $f_{h,P}(x, y)$ as

$$f_{h,P}(x, y) = \int \phi_{h_x}(x - \mu) \phi_{h_y}(y - \beta_0 - \beta_1 x) dP(\mu, \beta_0, \beta_1).$$

Suppose that $f_0(x, y)$ has compact support and all values of $(\mu, \beta_0, \beta_1, h_x, h_y)$ are in the weak support of Π . Then for all $\epsilon > 0$,

$$\Pi \left\{ P : \int f_0(x, y) \log \frac{f_0(x, y)}{f_{h,P}(x, y)} dx dy < \epsilon \right\} > 0.$$

Proof. This proof is similar to the one presented in Ghosal et al. (1999). Consider the case where x is scalar; this assumed for simplicity and can easily be extended to the vector-valued case. Fix $\epsilon > 0$. Assume $f_{0,h}(x, y)$ is as above. Note that

$$\int f_0(x, y) \log \frac{f_0(x, y)}{f_{h,P}(x, y)} = \int f_0(x, y) \log \frac{f_0(x, y)}{f_{0,h}(x, y)} + \int f_0(x, y) \log \frac{f_{0,h}(x, y)}{f_{h,P}(x, y)}. \quad (\text{A-2})$$

Using Theorem A-4, we can pick $h_{0,x}, h_{0,y}$ such that for every $h_x < h_{0,x}, h_y < h_{0,y}$,

$$\int f_0(x, y) \log \frac{f_0(x, y)}{f_{0,h}(x, y)} < \epsilon/2. \quad (\text{A-3})$$

Now we focus on the second term of Equation (A-2). Set

$$\mathcal{D} = [-x', x'] \times [-y', y'] \times [-y', y'].$$

Note that

$$\begin{aligned} & \int f_0(x, y) \log \frac{f_{0,h}(x, y)}{f_{h,P}(x, y)} \\ & \leq \int_{-x'}^{x'} \int_{-y'}^{y'} f_0(x, y) \log \frac{\int_{\mathcal{D}} f_0(\mu, \beta_0 + \beta_1 \mu) \phi_{h_x}(x - \mu) \phi_{h_y}(y - \beta_0 - \beta_1 x) d\mu d\beta_0 d\beta_1}{\int_{\mathcal{D}} \phi_{h_x}(x - \mu) \phi_{h_y}(y - \beta_0 - \beta_1 x) dP(\mu, \beta_0, \beta_1)} dx dy. \end{aligned}$$

Define

$$\mathcal{F} = \{ \phi_{h_x}(x - \mu) \phi_{h_y}(y - \beta_0 - \beta_1 x) : x \in [-x', x'], y \in [-y', y'] \}.$$

$\mathcal{F}$ is a set of functions in $(\mu, \beta_0, \beta_1) \in \mathcal{D}$; it is uniformly equicontinuous. Given this fact, we can use the Arzela-Ascoli theorem to find a finite tiling of (x, y) to approximate $g_0(x, y)$ arbitrarily well in the region $x \in [-x', x'], y \in [-y', y']$. The rest of the proof proceeds as in Ghosal et al. (1999). $\square$

Theorem A-5 can easily be extended to include scale mixtures of σ_x, σ_y (Ghosal et al. 1999, Tokdar 2006). Theorem 5.2 follows as a direct result of Theorem A-5.

All of the base measures proposed in Subsection 5.2 have weak support over the desired space, $\mathbb{R}^d \times \mathbb{R}^{d+1} \times \mathbb{R}_+^{d+1}$, and hence satisfy Theorem 5.2.

A-4 Proof of Theorem 5.3 and Results for Base Measures

We follow the same plan for sketching the proof of Theorem 5.3.

Theorem A-6. *Suppose that $f_0(x, k)$ has compact support. Define*

$$f_{0,h}(x, k) = \int f_0(\mu, k) \phi_h(x - \mu) d\mu.$$

Then,

$$\lim_{h \rightarrow 0} \int \int f_0(x, k) \log \frac{f_0(x, k)}{f_{0,h}(x, k)} dx dh = 0.$$

The proof is similar to that of Theorem A-4.

Theorem A-7. *Define $f_{h,P}(x, k)$ as*

$$f_{h,P}(x, k) = \int \phi_h(x - \mu) \frac{\exp(\beta_{0,k} - \beta_{1,k}x)}{\sum_{j=1}^K \exp(\beta_{0,j} + \beta_{1,j}x)} dP(\mu, \beta_{0,1}, \dots, \beta_{1,K}).$$

Suppose that $f_0(x, k)$ has compact support and all values of $(\mu, \beta_{0,1}, \dots, \beta_{1,K}, h)$ are in the weak support of Π . Then for all $\epsilon > 0$,

$$\Pi \left\{ P : \int f_0(x, k) \log \frac{f_0(x, k)}{f_{h,P}(x, y)} dx dk < \epsilon \right\} > 0.$$

Proof. Assume $f_{0,h}(x, k)$ is as above. Note that

$$\int f_0(x, k) \log \frac{f_0(x, k)}{f(x, k)} = \int f_0(x, k) \log \frac{f_0(x, k)}{f_{0,h}(x, k)} + \int f_0(x, k) \log \frac{f_{0,h}(x, k)}{f_{h,P}(x, k)}. \quad (\text{A-4})$$

Using Theorem A-4, we can pick h_0 such that for every $h < h_{0,x}$,

$$\int f_0(x, k) \log \frac{f_0(x, k)}{f_{0,h}(x, k)} < \epsilon/4. \quad (\text{A-5})$$

Now we focus on the second term of Equation (A-4). We can make $f_{0,h}(x, k)$ arbitrarily close to a density with bounded response probabilities that are still continuous in x . Choose $\gamma > 0$; for the sake of simplicity, assume $k = 1, 2$ (the outcome space can easily be expanded). Writing $f_0(x, k) = f_0(x) f_0(k|x)$, set

$$f_\gamma(k|x) = \begin{cases} f_0(k|x) & \text{if } f_0(k|x) \in [\gamma, 1 - \gamma], \\ \gamma & \text{if } f_0(k|x) \in [0, \gamma], \\ 1 - \gamma & \text{if } f_0(k|x) \in (1 - \gamma, 1]. \end{cases}$$

Then, for any $x \in [-x', x']$ and $k \in \{1, 2\}$,

$$\left| \frac{\int f_0(\mu) f_0(k|\mu) \phi_h(x - \mu) d\mu}{\int f_0(\mu) f_\gamma(k|\mu) \phi_h(x - \mu) d\mu} - 1 \right| < 2\gamma.$$

Note that

$$\begin{aligned} \int f_0(x, k) \log \frac{f_{0,h}(x, k)}{f_{h,P}(x, k)} &= \int f_0(x, k) \log \frac{f_{0,h}(x, k)}{f_{h,\gamma}(x, k)} + \int f_0(x, k) \log \frac{f_{h,\gamma}(x, k)}{f_{h,P}(x, k)}, \\ &\leq \int f_0(x, k) \log \frac{f_{h,\gamma}(x, k)}{f_{h,P}(x, k)} + 2\gamma. \end{aligned}$$

Finally, we approximate $f_{h,\gamma}$ by something that has the desired GLM form. Fix $0 < \delta < \gamma/(4K)$. Define

$$g_\delta(y_1, \dots, y_K | x) = \max \left(0, \delta \sum_{k=1}^K f_\gamma(k|x) - \sum_{k=1}^K \left| \frac{\exp(y_k)}{\sum_{j=1}^K \exp(y_j)} - f_\gamma(k|x) \right| \right),$$

for $y \in [-b, b]$ for some bound b . This produces a triangular box of “close” conditional probabilities around the true conditional probability. Define $f_{h,\gamma,\delta}$ as

$$\begin{aligned} f_{h,\gamma,\delta}(x, k) &= \int_{-x'}^{x'} \int_{[-b_0, b_0]^K} \int_{[-b_1, b_1]^K} f_0(\mu) \frac{g_\delta(\beta_{0,1} + \beta_{1,1}\mu, \dots, \beta_{0,K} + \beta_{1,K}\mu | \mu)}{\int_{[-b_0, b_0]^K} \int_{[-b_1, b_1]^K} g_\delta(\beta_0 + \beta_1 \mu, k | \mu) d\beta_0 d\beta_1} \\ &\times \phi_h(x - \mu) \frac{\exp(\beta_{0,k} + \beta_{1,k}\mu)}{\sum_{j=1}^K \exp(\beta_{0,j} + \beta_{1,j}\mu)} d\mu d\beta_{0,1} \dots d\beta_{1,K}. \end{aligned} \quad (\text{A-6})$$

Because $f_\gamma(k|x)$ is bounded away from 0 and 1, we can find finite b_0, b_1 such that

$$\max_{\beta_0 \in [-b_0, b_0]^K, \beta_1 \in [-b_1, b_1]^K} g_\delta(\beta_{0,1} + \beta_{1,1}x, \dots, \beta_{0,K} + \beta_{1,K}x) = \delta$$

for every $x \in [-x', x']$. Let L be the maximum Lipschitz constant of $f_0(k|x)$ for $x \in [-x', x']$; these exist because $f_0(k|x)$ is continuous in x , which has a compact domain. Then, observe that

$$\left| \frac{\int f_0(\mu) f_\gamma(k|\mu) \phi_h(x - \mu) d\mu}{f_{h,\gamma,\delta}} - 1 \right| \leq 2KL\delta.$$

Therefore,

$$\begin{aligned} \int f_0(x, k) \log \frac{f_{h,\gamma}(x, k)}{f_{h,P}(x, k)} &= \int f_0(x, k) \log \frac{f_{h,\gamma}(x, k)}{f_{h,\gamma,\delta}(x, k)} + \int f_0(x, k) \log \frac{f_{h,\gamma,\delta}(x, k)}{f_{h,P}(x, k)}, \\ &\int f_0(x, k) \log \frac{f_{h,\gamma,\delta}(x, k)}{f_{h,P}(x, k)} + \leq 2KL\delta. \end{aligned}$$

Set

$$\mathcal{F} = \left\{ \phi_h(x - \mu) \frac{\exp(\beta_{0,k} + \beta_{1,k}x)}{\sum_{j=1}^K \exp(\beta_{0,j} + \beta_{1,j}x)} : x \in [-x', x'], k \in \{1, \dots, K\} \right\}.$$

It is equicontinuous for $(\mu, \beta_0, \beta_1) \in [-x', x'] \times [-b_0, b_0]^K \times [-b_1, b_1]^K$; using this fact, we proceed in the same manner as in Theorem A-5. $\square$

Theorem 5.3 follows from Theorem A-7. As in the Gaussian example, all of the base measures given have sufficient weak support.

A-5 CMB Computational Details

The DP-GLM was run on the largest data size tested several times; log posterior probabilities were evaluated graphically, and in each case the posterior probabilities seem to have stabilized well before 1,000 iterations. Therefore, all runs for each sample size were given a 1,000 iteration burn-in with samples taken every 5 iterations until 2,000 iterations had been observed. The scaling parameter α was given a Gamma prior with an initial value set at 1. The means and variances of each component and all GLM parameters were also given a log-normal hyper distribution. The model was most sensitive to the hyper-distribution on σ_y , the GLM variance. Small values were used

($\log(m_y) \sim N(-3, 2)$) to place greater emphasis on response fit. The non-conjugate parameters were updated using the Hamiltonian dynamics method of Neal (2010).

Models with both conjugate and log-normal base measures were tried on this dataset. The conjugate base measure model did not capture heteroscedasticity well, so only the log-normal base measure was used for the remaining tests on this dataset.

This model was implemented in Matlab; a run on the largest dataset took about 500 seconds.

A-6 CCS Computational Details

Again, the DP-GLM was run on the largest data size tested several times; log posterior probabilities were evaluated graphically, and in each case the posterior probabilities seem to have stabilized well before 1,000 iterations. Therefore, all runs for each sample size were given a 1,000 iteration burn-in with samples taken every 5 iterations until 2,000 iterations had been observed. The scaling parameter α was given a Gamma prior with an initial value set at 1. The hyperparameters of the conjugate base measure were set manually by trying different settings over four orders of magnitude for each parameter.

All base measures were conjugate, so the sampler was fully collapsed. α was updated using Hamiltonian dynamics (Neal 2010). Original results were generated by Matlab; the longest run times were about 1000 seconds. This method has been re-implemented in Java in a highly efficient manner; the longest run times are now under about 10 seconds. Run times would likely be even faster if variational methods were used for posterior sampling (Blei and Jordan 2005).

A-7 Solar Computational Details

Again, the DP-GLM was run on the largest dataset size tested several times; log posterior probabilities were evaluated graphically, and in each case the posterior probabilities seem to have stabilized well before 1,000 iterations. Therefore, all runs for each sample size were given a 1,000 iteration burn-in with samples taken every 5 iterations until 2,000 iterations had been observed. The scaling parameter α was set to 1 and the Dirichlet priors to $Dir(1, 1, \dots, 1)$. The response parameters were given a Gaussian base distribution with a mean set to 0 and a variance chosen after trying parameters with four orders of magnitude.

All covariate base measures were conjugate and the β base measure was Gaussian, so the sampler was collapsed along the covariate dimensions and used in the auxiliary component setting of Algorithm 8 of Neal (2000). The β parameters were updated using Metropolis-Hastings. Results were generated by Matlab; run times were substantially faster than the other methods implemented in Matlab (under 200 seconds).
